

Lecture 12:

Encryption in Practice

6.1600 - Fall 2022

MIT

C-G, Kalai,

Zeldovich 

Plan

- * File encryption
- * Encrypted streams: TLS
- * Encrypted messaging

Theme: Gap between properties that apps want & properties that standard schemes provide.

Logistics

- Midterm 10/26
- OH Monday 3-4pm
32-G970

Recap: Encryption

* Weak (CPA-secure) enc, fixed-len msgs, shared key

↳ Counter mode

* " " " var-len msgs "

↳ Enc-then-MAC

* Strong (CCA-secure) enc, " "

↳ DH Key Exchange

* " " " " " Without a shared key

Today: Applications

Next time: Privacy/Crypto problems that encryption doesn't solve.

Surprise!

→ With CRHFs, MACs, Signatures
AE, DH, PKE

you have the tools to understand essentially
every widely used cryptographic protocol.*
(exception, NSA, lattices, blockchain, ...)

→ There really are not that many primitives
in use in our systems.

BUT: As you'll see, the designs/specs are
still very complicated. (TLS 1.3 = 160 pages)

Why?

↳ Extra security & functionality properties

↳ less often, but sometimes: Sloppy design

↳ Also, you'll see rules violated → often attacks

File Encryption

↳ Essentially what we've already seen.

↳ Bottom line: Use authenticated encryption AES-GCM

Example:

WhatsApp Encrypted Backup
(msgs, contact, ...)

- Phone picks a secret AES key k

- $ct = \text{AES-GCM}(k, \text{data})$

↳ sent to WhatsApp

- User saves key k (64 dec digits)

[There's a more complicated option that encrypts using a password... uses hardware security device... more complicated.]

↳ Will discuss in context of iPhone

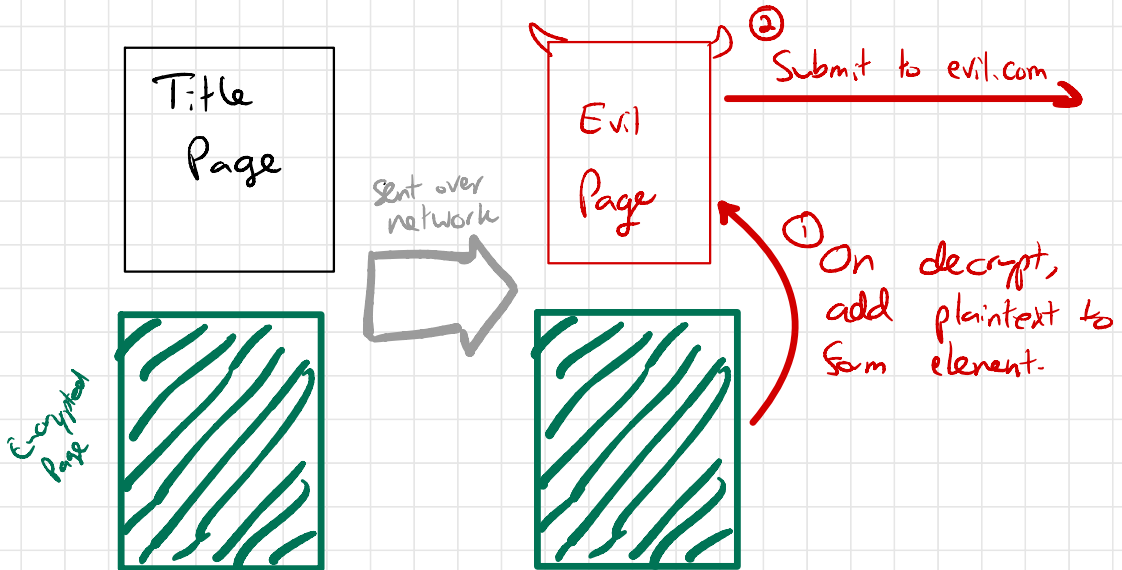

Even file encryption can be tricky...

(See pdf-insecurity.org)

Example: PDF v1.5

- * PDF format allows password-encrypting some/all pages of doc — uses $\text{Hash}(\text{password})$ as AES key.
- * PDF supports submitting form to external server via HTTP
- * PDF forms can referena objects in doc
- * PDF supports submit form on event (open, click, close)

→ Each seems fine on its own but together they allow an attacker to learn encrypted data.

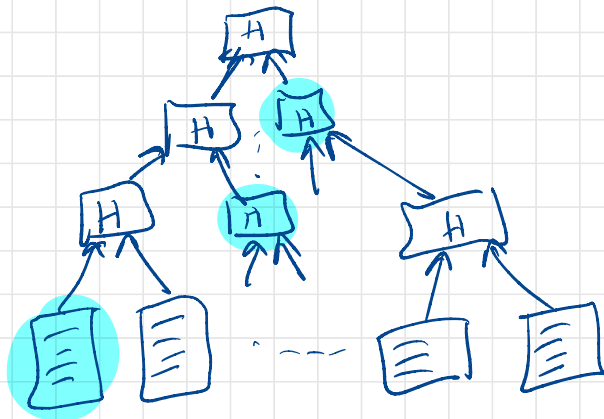

Moral?

- * As soon as you depart from the standard simple thing, you open the door to all sorts of subtle attacks...
- * Authenticating control info / metadata is as important as authenticating the data itself.

What would have prevented this attack?

- MAC over entire PDF?
- Compatible w/ wanting to be able to load one page at a time?

↳ Maybe Merkle tree over pages & MAC on root.

Stream Encryption: TLS { Transport Layer Security (Formerly SSL)

Vision:

CLIENT

"Encrypted & authenticated pipe"

SERVER

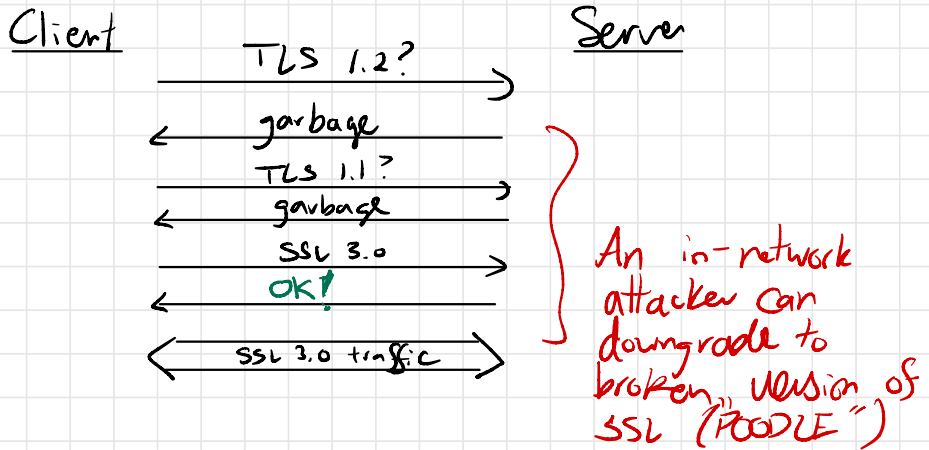

* Uses certificate-based pub key infrastructure to map domain name (mit.edu) → sig verify public key.

When you use HTTPS, SMTPS, IMAPS, ... you are running the original protocol (e.g. HTTP) over TLS.

* Seems simple! Very hard to get right...
Many attacks & patches since first versions.
MORAL: Use TLS 1.3 - don't try it yourself.

Why is this hard?

- Version/protocol negotiation - client and server may support different algs, protocols
↳ Downgrade attacks

- More complex protocol → more complex security goals
- FEATURES! Everyone wants to add something extra (e.g. client certificate auth at MIT)

Structure of TLS (v1.3)

I. Handshake (key exchange)

II. Record protocol

TLS Handshake: Properties

There are eight in the RFC!

- * Correctness
 - * Security — adv "learns nothing" about session key → we saw this before
 - * Peer authentication — each party believes they're talking to the other
 - * Downgrade protection — parameters chosen should be the same w/ no attacker
 - * Forward secrecy w.r.t. key compromise
 - ↳ If attacker compromises client/server, it cannot decrypt past traffic.
- N.B. Vanilla DH doesn't provide forward secrecy
- * Protection vs. key compromise impersonation
 - * Protection of endpoint identities

TLS Handshake

*Grossly simplified!

Client (pk_{CA})

$r_c \leftarrow \{1, \dots, n\}$

Client Hello

- random values
 - ciphers supported, $R_c = g^{r_c} \in G$
- (think: diff primes for DH key ex)

(cert_{MIT})
mit.edu (sk_{MIT})

$s \leftarrow \{1, \dots, n\}$

Server Hello

- random values
- cipher to use, $R_s = g^{r_s} \in G$

Choose cipher suite to use.

Complete DH exchange.

Server certificate for mit.edu

Signature over msgs server has seen so far. using sk_{MIT}

Encrypted with key derived from $g^{r_c r_s}$

Check cert against CAS

check sig

$k = H(g^{r_c r_s})$

$k = H(g^{r_c r_s})$

Send application data using keys derived from k.

↳
↳
↳

↳
↳
↳

- Why replay attacks isn't possible.

↳ random values change every protocol run

- Why send server cert only after establishing shared DH secret?

↳ Hides cert from passive network attacker (doesn't necessarily learn which Akamai-hosted site you're visiting)

- Why does this provide forward secrecy?

↳ Only use long-term secrets to sign

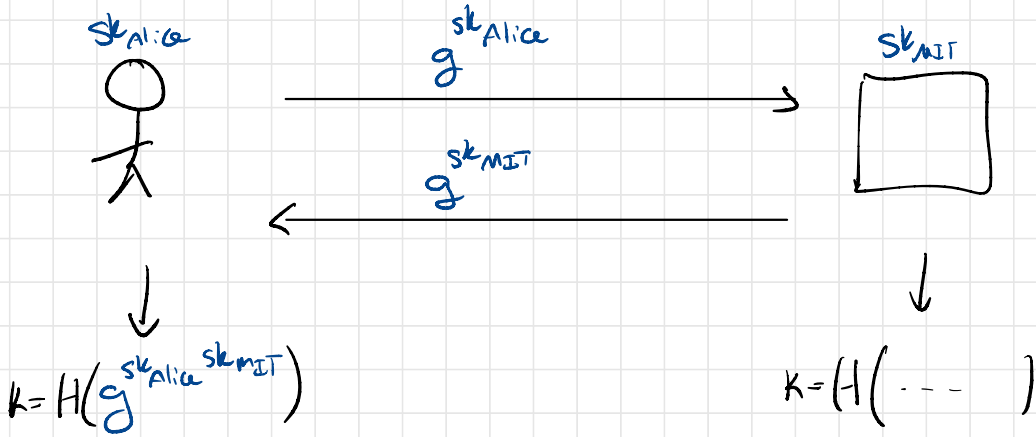

↳ Delete the DH secret keys after handshake completes.

[N.B. This doesn't protect past traffic against eavesdropper w/ his quantum comp.]

Key-Compromise Impersonation Attack

At MIT we use client certificates.

A bad way to do a handshake is this:

Problem: If attacker compromises Alice's secret key, attacker can pretend to be MIT to Alice.

- With sk_{Alice} , attacker can already make problems.
- But by impersonating MIT, attacker can trick Alice into sending more data. (passwd, etc.)

Properties that TLS doesn't provide

Authenticated EOF

- TLS makes data available to app as it arrives
- Needed for many uses (Youtube, etc.)
- But counterintuitive consequences:

```
curl https://sh.rustup.rs | sh
```

```
↳ rm -rf /tmp/install...
```

~~✗~~ CUT!

... what is the right thing to do here?

Hiding length of plaintext

Reasonable thing to do: gzip data before sending it to TLS (used to be standard).

Problem: Attacker controlled data often sent in same stream as secrets. Esp in web

CRIME Attack: Exploiting fact that TLS doesn't hide msg lengths

Goal: Steal user's Google cookie ... secret auth string sent with every request.

... Read cookie one byte at a time!

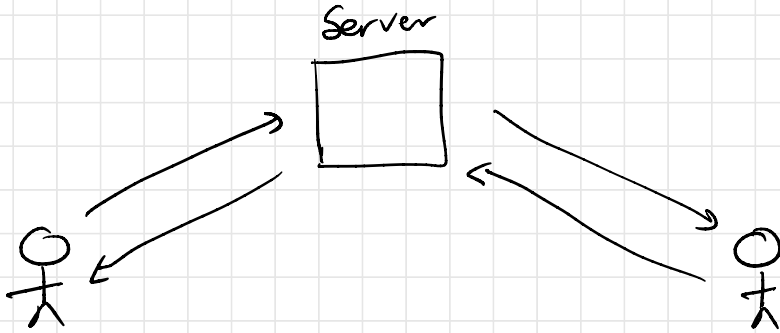

"Solution": Disable compression in TLS
... still affects HTTP

Moral: Use TLS 1.3 whenever you need "encrypted TLS"

Be aware of its pitfalls.

Encrypted Messaging

Think: Signal, WhatsApp, iMessage, ...

Why different from stream setting?

- * "Connections" are long lived - for years
- * Little data, few connections
- * non-interactive - either party can be offline for long periods

Goals: Many as in TLS (though underspecified)

eg. Forward Secrecy

"Post-Compromise Security" - If attacker gets a snapshot of your device, will eventually not be able to read msg.

↖ Not clear how relates to real-world threat

Unlike TLS, these apps typically rely on a centralized key server.

If someone compromises the key server, very weak protection against active attack.

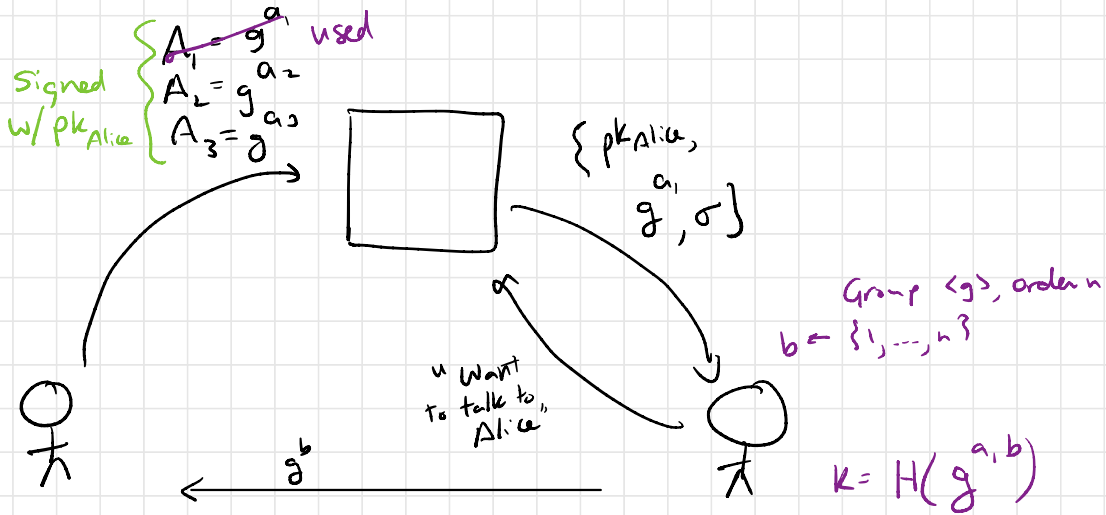

* Phone can show you hash of claimed pk Bob ... check manually. "No one" does this

* App can give warning when pk Bob changes

↳ "Everyone" ignores this

↳ For sec-conscious users, maybe these suffice?

Toy Key Exchange

N.B. Server learns who is talking to whom.

Toy Ratchet - How to get forward secrecy and post-compromise security.

Alice (k)

proxied via server

Bob (k)

$a_1 \leftarrow \{1, \dots, n\}$
delete k

$g^{a_1}, E(k, \text{msg})$

$b_1 \leftarrow \{1, \dots, n\}$

$k_1 \leftarrow \text{Hash}(k, g^{a_1 b_1})$
delete k, k_1

$g^{b_1}, E(k_1, \text{msg})$

$a_2 \leftarrow \{1, \dots, n\}$

$g^{a_2}, E(k_2, \text{msg})$

$b_2 \leftarrow \{1, \dots, n\}$
 $k_2 \leftarrow \text{Hash}(k_1, g^{a_2 b_2})$
 $k_3 \leftarrow \text{Hash}(k_2, g^{a_3 b_3})$
delete b_1, k_2

$k_1 \leftarrow \text{Hash}(k, g^{a_1 b_1})$
 $k_2 \leftarrow \text{Hash}(k_1, g^{a_2 b_2})$
delete a_1, k_1

$g^{b_2}, E(k_3, \text{msg})$

⋮

- An attacker who compromises device cannot recover past msgs
- Without persistent compromise, protocol will "heal" security

* Big advances in encrypted comms
in last ~10 yrs

↳ Before that: not much TLS,
not much enc missing

* Next time: Open problems...
what we havent solved.

The
End!
